Planar Trinet Dynamics with Two Rewrite Rules

tommaso.bolognesi@isti.cnr.it

A deterministic network mobile automaton is proposed for the creation of planar trivalent networks (trinets) based on the application of only two simple rewrite rules. The possible Brownian dynamics of the control point are enumerated and explored. A useful behavioral complexity indicator is introduced, called the revisit indicator, exposing a variety of emergent features, involving periodic, nested, and random-like dynamics. Regular structures obtained include one-dimensional graphs, oscillating rings, and the two-dimensional hexagonal grid. In two cases only, out of over a thousand that were inspected, a remarkably fair, random-like revisit indicator is found, with trinets that exhibit a slow, square-root growth rate. Some properties of these surprising computations are investigated. Finally, one two-dimensional case is found that seems to be unique in the way regularity and randomness are mixed.

1. Introduction

Stephen Wolfram [1] supports the “digital physics” view, according to which the ultimate laws of physics are of a computational nature, the entire history of our universe is the output of a small, possibly deterministic program, and all simple and complex natural phenomena correspond to emergent properties of this universal computation. In particular, he suggests that physical space could be a giant trivalent network that evolves according to a few simple rewrite rules. Trivalent networks (trinets) are finite, undirected graphs where each node has exactly degree 3, that is, three neighboring nodes. It is easy to realize that trinets are sufficient for implementing graph structures of any complexity: given a graph with unrestricted node degrees, the basic trick is to replace any node $x$ of degree $n$ by a cycle $X$ of $n$ nodes of degree 3, each connected to a neighbor of $x$. In particular, let $k$ be the dimensionality of a graph $G$ whenever the number of nodes reachable from a generic node of $G$ in at most $r$ steps (edges) grows like $r^k$. Examples of regular trinets of dimensionality 1, 2, and 3, and of planar trinets with fractal dimensions between 1 and 2 are shown in [1, pp. 477 and 509].
In general, graph rewriting involves nondeterminism, in the selection both of a rule and of a place to apply it. Various trinet rewrite rules, and policies for eliminating nondeterminism, are discussed in [1]. One solution is to restrict to causal-invariant rewrite systems, which generate a unique partial order of rewrite events, regardless of the order in which rules are applied. Another solution enriches the rewrite process by state information that records the “age” of nodes, and then always selects the rule and location that involves, say, the youngest nodes. Causal invariance is a powerful and elegant concept, but the search for systems of rules that guarantee this property is hard, unless quite restrictive sufficient conditions are adopted; and the mechanism of time stamps appears as unnatural as, say, the synchrony assumption for the updating of an unbounded set of cells, as adopted by cellular automata. (See [1] for a detailed description of these two approaches, which we have already assessed in [2].)

A third solution for reducing nondeterminism is to adopt what Wolfram calls network mobile automata: these consist of setting up a single active node, letting rules replace clusters of nodes around it, and moving control to an adjacent node. However, despite looking at several hundred thousand cases involving clusters with up to four nodes and four dangling links, Wolfram reports that he has not been able to find automata with especially complicated behavior, which explains why this model is relegated to a small note on page 1040 in [1]. In conclusion, none of the experiments on network evolution described by Wolfram could fully replicate the success achieved by elementary cellular automata, with their visually appealing, rich variety of emergent properties, and with their ability to create interacting particles, as observed in the well-known rule 110 computations.

The two related objectives of this paper are to: (i) further explore algorithms for the evolution of trinets and (ii) visually identify effective complexity indicators and techniques that can help screen large spaces of trinet-based computations. In pursuing the first objective, we avoid the difficulties related with causal invariance, and refrain from enriching the structure of trinets by state information. Rather, a trinet growth algorithm is devised along the lines of network mobile automata. Here is a summary of the major differences with the approach (cursorily) mentioned by Wolfram in [1].

1. We use an extremely small set of rewrite rules, consisting of only two elements.
2. We restrict the study to planar trinets.
3. We adopt a refined notion of control point called the focus that is described later.
4. We attribute more importance to the dynamics of the latter, whose steps are also dependent on the applied rewrite rule.

Furthermore, the algorithm is designed around the manipulation of trinet duals, a choice that has to some extent facilitated the identifica-
tion and exhaustive exploration of policies for control point movement.

In Section 2 we introduce our planar trinet growth algorithm, with its two rewrite rules, and its three parameters, one of which, the Threshold, induces a convenient classification of our computational space. In Section 3 we discuss a few ways in which the overall character of a trinet computation can be visualized, and introduce a useful revisit indicator. Based on this technique, we exhaustively explore our computational classes in Sections 4 through 9, which correspond to increasing values of the threshold parameter, and describe the progressive appearance of various emergent features. In Section 10 we summarize our results and discuss items for future work. A preliminary presentation of this work was provided in [3].

Similar to the space of (elementary) cellular automata, the space of trinet computations, as created by our algorithm, offers such an abundance of aspects to be investigated that a single paper cannot cover all of them in depth. Thus, the purpose of this work is to provide a first exploration of the whole computation space, identify all features that may possibly emerge in it, and single out the most interesting cases. We believe that these results shall trigger a number of specific questions that we look forward to investigating in forthcoming papers.

## 2. The Algorithm

A trinet is an undirected graph where each node has degree 3. Trinets may include loop edges and double edges, and, if \( v \) is the number of vertices (nodes) and \( e \) is the number of edges, then \( 3v = 2e \). The proof is simple. By definition, each node is connected to three distinct edges, or to a loop edge and a “normal” one. By charging three edges to each node, via the incidence relation, we count each edge exactly twice, thus establishing the given equation. Note that a loop edge contributes two units to a node degree. Two consequences of the equation \( 3v = 2e \) are that \( v \) is a multiple of 2 and \( e \) is a multiple of 3.

A graph is simple when it does not include loop edges or double edges. Our algorithm shall only handle trinets without loops, but possibly with double edges, called trinets with doubles (but we shall often omit the attribute). The inclusion of loops introduces further difficulty, but appears interesting, and is left for future investigation. A graph is planar when it can be embedded on the surface of a sphere with no edge crossings. An embedding partitions the surface of the sphere into regions, and induces a dual graph (also planar), in which nodes correspond to regions and edges connect the nodes representing adjacent regions. Note that there is an obvious one-to-one correspondence between the edges of a planar graph and those of its dual.

If \( T \) is a planar trinet with doubles, and \( D \) is its dual (see Figure 1, where the two graphs have, respectively, black and white nodes), then:
regions in $T$ will be delimited by at least two edges, thus nodes in $D$
have at least degree 2 (Figure 1(a));

$D$ may include both loops and doubles (Figures 1(c) and 1(d));

all the regions of $D$ are triangles, formed by three distinct edges, and
every edge is shared by two distinct triangles (recall that one of them
may be the external, “infinite” triangle).

The last fact is established by realizing that the dual of $D$ is $T$ itself,
so that nodes of $T$, with degree 3, represent faces of $D$, with three
sides; and the two triangles sharing an edge in $D$ are distinct essen-
tially because there are no loop edges in $T$.

Graph $D$ may include degenerate triangles formed by three distinct
edges but less than three nodes. For example, in Figure 1(c), the loop
edge in the dual graph delimits a finite triangle with two nodes only,
while the infinite, external region of the dual graph of Figure 1(d) is a
triangle with just one node. (The inclusion of loop edges in trinets
would lead to degenerate triangles with two vertices and two edges
only.) Note, finally, that a loop edge in $D$ corresponds to an edge in $T$
whose removal disconnects the trinet (Figures 1(c) and 1(d)).

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{figure1.png}
\caption{Four planar trinets (black nodes) and their duals (white nodes).}
\end{figure}

In our algorithm we shall handle planar graphs—trinet duals—
with a specific embedding on the sphere. For doing this, node adja-
cency information is not enough: we need to keep the list of triangles
that form the embedding, as described next.
2.1 Representation of Spherical (Planar) Graph Embedding

We take now a closer look at the representation and properties of the spherical (planar) graph embeddings manipulated by the algorithm, as a basis for describing the algorithm itself and proving its invariant.

2.1.1 Definitions: Oriented Edge, Oriented Triangle, Sphericity Conditions, and Spherical Set of Oriented Edge Triples

Let $G(V, E)$ be a connected, undirected graph, where $V$ is the set of $v$ vertices and $E$ is the set of $e$ edges. Let $ex(p, q)$ denote an oriented edge, where $ex \in E$ is an edge incident to vertices $p$ and $q$, and $(p, q)$ is an ordered pair. A triple of oriented edges is an oriented triangle (shortly, a triangle) when (i) it is formed by three distinct edges; that is, $ex \neq ey \neq ez \neq ex$, and (ii) its elements can be arranged as in $(ex(p, q), ey(q, r), ez(r, p))$ thus creating a cycle of (at most) three different nodes. Which oriented edge appears first in the triple is irrelevant. Node symbols $p$, $q$, and $r$ are understood as formal variables, some of which could be assigned the same actual node identifier, thus yielding degenerate triangles. A set of $t$ oriented edge triples, relative to sets $V$ and $E$, is called spherical when it satisfies these three sphericity conditions.

1. Every triple is an oriented triangle.

2. Every edge is shared by two distinct triangles, with associated node pairs appearing in opposite order; that is, $ex(p, q)$ and $ex(q, p)$.

3. $v - e + t = 2$ (Euler’s formula).

Based on graph theoretic arguments, the following fact can be easily established.

**Proposition 1.** If $G(V, E)$ is a connected, undirected graph, for which a spherical set of triples can be built, then $G$ is planar, and every node has at least degree 2. The triples then describe the counterclockwise (by arbitrary convention) traversal of the border of the triangular regions of the spherical embedding of $G$.

In particular, the minimum degree 2 is a direct consequence of sphericity condition 1. And, based on conditions 1 and 2, it is readily established that $3t = 2e$ which, combined with Euler’s formula, yields

$$
e = 3v - 6$$

$$t = 2v - 4$$

(1)

(If condition 3 is replaced by the more general Euler-Poincaré formula $v - e + t = 2 - 2g$, we have sufficient conditions for embedding graphs on two-manifolds of genus $g$. For example, when $v - e + t = 0$ the graph can be embedded, without edge crossings, on the torus, whose genus is 1.)
2.2 Initial Configuration, Rewrite Rules, and Computation Step

2.2.1 Initial Configuration

The most elementary trinet with doubles is the 2-node, 3-edge graph shown in Figure 1(a); thus, all our computations shall start from the corresponding triangular dual graph shown at its right, whose triangular, spherical embedding is

\[
\text{triangles} = \{(e1(1, 2), e2(2, 3), e3(3, 1)), \\
(e1(2, 1), e3(1, 3), e2(3, 2))\}. 
\]

One can indeed check that the given data structure satisfies the three sphericity conditions.

2.2.2 Rewrite Rules

The two rewrite rules used by our algorithm are illustrated in Figure 2, where the transformation of dual graphs is emphasized.

![Figure 2. Planar trinet rewrite rules: Refin (upper), Diags (lower).](image)

In the context of our algorithm, these rules are called, respectively, *Refin* and *Diags*, since the former refines a triangle by partitioning it into three new triangles, and the latter flips the diagonal of a rhombus. These are among the simplest rules considered in [1] (p. 509), where their completeness is pointed out: they are sufficient for transforming any planar trinet into any other (with *Refin* used both ways).
Our implementation of these rules operates on sets of oriented triangles. The rule \textit{Refin} removes a triangle and creates three new triples, by introducing a new node \((s)\) and three new edges \((e4, e5, e6)\):

removed triangle: \((e1(q, r), e2(r, p), e3(p, q))\)

created triples: \((e1(q, r), e4(r, s), e6(s, q))\),
\((e2(r, p), e5(p, s), e4(s, r))\),
\((e3(p, q), e6(q, s), e5(s, p))\).

The rule \textit{Diags} removes two triangles sharing an edge \((e3)\), and introduces two new triples:

removed triangles: \((e1(q, r), e2(r, p), e3(p, q))\),
\((e3(q, p), e4(p, s), e5(s, q))\).

created triples: \((e5(s, q), e1(q, r), e3(r, s))\),
\((e3(s, r), e2(r, p), e4(p, s))\).

Again, \(p, q, r, \) and \(s\) are understood as formal variables, which may refer to the same actual node.

\subsection{Computation Step}

The algorithm endlessly iterates an elementary computation step, starting from the initial condition described earlier. The step is illustrated in Figure 3 and accepts the tuple \((\text{trinetDual}, \text{focus}, \text{Threshold}, \text{RefinCode}, \text{DiagsCode})\) and returns the tuple \((\text{trinetDual}', \text{focus}', \text{Threshold}, \text{RefinCode}, \text{DiagsCode})\), where:

- \textit{trinetDual} is the current graph, the dual of a trinet, represented as a set of triangles.
- \textit{focus} is an angle of a specified triangle in \textit{trinetDual}, and represents the current location for control.
- \textit{Threshold} is a constant natural number in the interval \([3, \infty]\). The choice between rules \textit{Refin} and \textit{Diags} depends on the degrees of nodes \(p\) and \(q\) on the edge facing the \textit{focus}: when the degree of \(p\) or \(q\) is lower than the \textit{Threshold}, then rule \textit{Refin} is applied, which increments by one the degree of both nodes; otherwise rule \textit{Diags} is applied, which decrements their degrees by one.
- \textit{RefinCode} and \textit{DiagsCode} are constant parameters, ranging, respectively, in intervals \([1, 18]\) and \([1, 9]\); they are used for choosing \textit{focus}'s, the next focus, as shown in the lower part of Figure 3. In light of the symmetry of the initial graph, we can optimize the parameter space by dropping half of the 18 potential choices of the new focus, after rule \textit{Diags} has been applied: we shall therefore consider only \(18 \times 9 = 162\) pairs of values for these two parameters.
- \textit{trinetDual}' and \textit{focus}' are the updated values of these variables, used for iterating the computation step. \textit{Threshold}, \textit{RefinCode}, and \textit{DiagsCode} are constants; thus, they are unchanged by the step.
### 2.3 Algorithm Invariant

We now want to prove that the rewrite rules, as implemented, preserve the sphericity, as defined previously, of the data structure they manipulate. For doing this we need to introduce a method for computing the degree of a node in a triangular, spherical embedding. If \( n \) is the number of occurrences of node \( p \) in a set of oriented triangles, then degree(\( p \)) = \( n/2 \), since each edge occurs twice in the structure (recall that a loop edge \( e(p, p) \) contributes two units to degree(\( p \))). As an alternative, we may traverse all edges incident to \( p \) while rotating clockwise around \( p \), as follows: pick from the set of triples an oriented edge \( e(n1, p) \) in which \( p \) appears as the second node, and compute what we call the cyclic star path:

\[
e(n1, p), f(p, n2), f(n2, p), g(p, n3), ..., e(p, n1)
\]

in which two adjacent elements with different edge identifiers, for example, \( e(n1, p) \) and \( f(p, n2) \), represent edges that share node \( p \) and
appear in (cyclic) sequence in some triangle, while adjacent elements with the same edge identifier, for example, \( f(p, n2), f(n2, p) \) represent two opposite traversals of the same edge, as found in two distinct triangles. It is easy to check that degree\((p)\) is half the length of the star path around \( p \).

As an example, consider the list of two oriented triangles representing the initial configuration of equation (2). The cyclic star path for, say, node 1 is: \( e3(3, 1), e1(1, 2), e1(2, 1), e3(1, 3) \). This yields degree\((1) = 2 \). The advantage of this technique is that it allows us to possibly discover the degree of a node without scanning the whole list of triangles. We are now ready to prove an important invariant of the algorithm.

**Proposition 2 (Algorithm invariant).** When applied to a spherical set of triangles, and when \( \text{Threshold} \geq 3 \), the step of our algorithm produces another spherical set of triangles.

**Proof.** We must prove that when a set of triples satisfies sphericity conditions 1 through 3, then the set of triples obtained from it after one step also satisfies the conditions. We shall refer to the edge and node identifiers appearing in the rule implementations described in equations (3) and (4). We distinguish two cases.

**Case 1: Rule Refin is applied.** Each of the three triples created by this rule is an oriented triangle by construction, so condition 1 is preserved. Furthermore, these triangles: (i) reintroduce the instances \( e1(q, r), e2(r, p), e3(p, q) \) that were removed, so that each of these “old” edges is shared precisely by a new and an old triangle, and (ii) collectively introduce two oriented edge occurrences, with opposite node orderings, of each new edge \( (e4, e5, e6) \), so that each new edge is shared by two of the new triangles; thus, condition 2 is also preserved. Finally, \( v, e, t \) are incremented, respectively, by 1, 3, 2, so that the value of \( v - e + t \) is unaffected and condition 3 is preserved. The effect of \( \text{Refin} \) on a triangle involving one, two, or three distinct vertices is illustrated in Figure 4.

![Figure 4](image_url)

*Figure 4.* Applying the rule \( \text{Refin} \) to triangles with three vertices, two vertices, or one vertex.
Case 2: Rule Diags is applied. Consider the two removed triangles. They share at least edge e3, but may share more; again, symbols e1, e2, e4, and e5 are understood as formal variables, some of which may assume the same actual value. Thus, we distinguish three cases, depending on the number of actual edges shared. In all these cases condition 3 is trivially guaranteed, since the counts of vertices, edges, and triples is left unchanged.

Case 2.1: The two removed triangles share one edge. Since e1, e2, e4, and e5 are all different, each of the two created triples is a triangle by construction; hence, condition 1 is guaranteed. Condition 2 is guaranteed by the fact that oriented edge occurrences for e1, e2, e4, e5 are only moved around by the rule, while occurrences e3(p, q) and e3(q, p) are replaced by occurrences e3(r, s) and e3(s, r) that still appear in different triangles.

Case 2.2: The two removed triangles share two edges. We distinguish two subcases.

Case 2.2.1: The two shared edges (one is e3) appear in the same order in the two removed triangles. Let us then assume, without loss of generality, that e1 = e4 (the case e2 = e5 is symmetric), so that the two removed triangles can be written:

\[(e1(q, r), e2(r, p), e3(p, q))\]
\[(e3(q, p), e1(r, q), e5(q, q)),\]

where the second triple is obtained by reversing the order of nodes for e1 and e3, and by letting the nodes for e5 complete the triangulation. But for the second triple to be a correct triangle, it must also have p = r, so that the triangles can be rewritten as:

\[(e1(q, p), e2(p, p), e3(p, q))\]
\[(e3(q, p), e1(p, q), e5(q, q)).\]

These triangles are depicted in Figure 5(a). By applying the rule Diags to these two oriented triangles, we obtain the two triples:

\[(e5(q, q), e1(q, p), e3(p, q))\]
\[(e3(q, p), e2(p, p), e1(p, q)).\]

We have obtained two oriented triangles (condition 1), and it is trivial to verify that, after the replacement, condition 2 holds.

Case 2.2.2: The two shared edges (one is e3) appear in opposite order in the two removed triangles. Let us then assume, without loss of generality, that e1 = e5 (the case e2 = e4 is symmetric). The two triangles to be removed are:

\[(e1(q, r), e2(r, p), e3(p, q))\]
\[(e3(q, p), e4(p, r), e1(r, q)),\]

where the second triple is obtained by reversing the order of nodes for e1 and e3, and by letting the nodes for e4 complete the triangulation. Consider node q, which is shared by the two edges e1 and e3, in turn

Complex Systems, 18 © 2008 Complex Systems Publications, Inc.
shared by the two triangles: its cyclic star path is \((e3(p, q), e1(q, r), e1(r, q), e3(q, p))\) and its length is 4, thus degree\((q) = 2\). This is in conflict with the assumption \(\text{Threshold} \geq 3\): the rule \(\text{Diags}\) could not be applied to edge \(e3\) since one of its nodes has a lower degree than the threshold. The two triangles are depicted in Figure 5(b).

![Figure 5. Pairs of triangles for (a) case 2.2.1 and (b) case 2.2.2.](image)

**Case 2.3:** The two removed triangles share three edges. The first removed triangle is \((e1(q, r), e2(r, p), e3(p, q))\), thus the second removed triangle must be composed of the three oriented edges \(e1(r, q), e2(p, r),\) and \(e3(q, p)\); thus, it can only be \((e1(r, q), e3(q, p), e2(p, r))\). In this case, the star path of any of the nodes has length 4; hence, all nodes have degree 2. This is, again, in conflict with the assumption \(\text{Threshold} \geq 3\).

We verified earlier that the set of triples in the initial configuration is spherical. In light of the given invariant, we now conclude, inductively, that all sets of triples produced by the algorithm are spherical; that is, they represent spherical embeddings of planar, triangular graphs.

### 2.4 Computation Classes

We let \(c[T, \{RC, DC\}, L]\) denote the \((L - 1)\)-step computation of our algorithm, starting from the initial condition of equation (2), with \(\text{Threshold} = T, \text{RefinCode} = RC,\) and \(\text{DiagsCode} = DC\). (A pedantic but necessary clarification: usually a *step* is understood as a *pair* of consecutive states; hence, a 1-step computation is two states long: the “\(L\)” in \(c[T, \{RC, DC\}, L]\) refers to the *Length* of the computation, intended as the number of states it includes.) We shall also use a convenient notation for representing subsets of the computation space. For example, \(C[\text{Threshold} = 3]\) denotes the set \(\{c[3, \{RC, DC\}, S] | \text{RC} \in [1, 18], \text{DC} \in [1, 9], S \geq 1\}\), that is, the family of all computations with \(\text{Threshold} = 3\), of any length. Since we impose
Threshold $\geq 3$, the first computation step inevitably applies the rule \textit{Refin} and produces the tetrahedron graph shown in Figure 1(b). Then computations start to differentiate depending on the parameter settings.

3. Visual Indicators for Planar Trinet Computations

A computation can be defined as a sequence of states. The state of our algorithm is essentially formed by the pair of variables (\textit{trinetDual}, \textit{focus}) that represent a planar graph and the location of control in it. We are interested in the emergent properties of planar trinets, with the idea that they might eventually capture properties of physical space. However, it may be hard to visually detect emergent properties when directly using graphs for the following reasons: (i) a trinet or trinet dual may soon become a complex structure, and a sequence of thousands of them can hardly be inspected at a glance, as opposed to what happens, for example, with the computations of elementary cellular automata; (ii) there exist many alternative methods to draw graphs on the plane, such as using a predefined arrangement of the nodes (e.g., circular) or applying attractive or repulsive forces to nodes, and the emergence and detectability of patterns is largely dependent on the method.

One can of course look just at the final graph, either in dual or in primal form, as we do later. However, emergent properties are better detected when looking at the whole computation. Thus, in our investigation we are interested in the fluctuations of the other state variable: the \textit{focus}. This variable captures only a tiny fraction of state information, but this is indeed an advantage, since we can easily plot a whole computation as a compact, readily inspected diagram. We have defined the \textit{focus} as the angle $\{e1, e2\}$ between two edges of triangle $\{e1, e2, e3\}$. For further simplification, we simply monitor the edge opposite to this angle, namely, $e3$. Note that this is the edge whose vertices $p$ and $q$ are tested at every step: we call it the \textit{current edge}. Looking at $e3$ rather than at the pair $\{e1, e2\}$ introduces further ambiguity, or abstraction, since $e3$ identifies \textit{two} possible foci. And yet, the sequence of current edge identifiers turns out to be a useful indicator. New edges are created in the trinet dual, three at a time, only by the \textit{Refin} rule, and are assigned progressive natural numbers; plotting the sequence of current edge numbers reveals the extent to which the control point can revisit and update old parts of the graph and whether some regions are definitively abandoned. For this reason we call these numeric sequences, and their plots, \textit{revisit indicators}.

For illustrating the idea, and for comparison with some of the revisit indicators discussed later, consider the two plots in Figure 6. These depict the revisit indicators for two extremely simple and regular graph growth patterns; the relevant revisited elements are now the
nodes, which are numbered sequentially as they are created. In the first case the algorithm maintains a linear topology, and creates a new node only after having sequentially scanned the current list \(\{1, 2, \ldots, n\}\) of nodes, in both directions, up and down. The second case is similar, except that nodes are arranged in a growing circle, and a new node is added after a circular, single-scan visit of the graph.

![Figure 6](image)

**Figure 6.** Revisit indicators for graphs with (a) linear and (b) circular topology.

An easy calculation shows that the node-growth functions, also plotted in the diagrams, are \(n = \sqrt{s}\) for the linear graph, and \(n = \sqrt{2s}\) for the circular graph. More generally, a growth rate \(n = \sqrt{2s/k}\) corresponds to a “grow-and-revisit” algorithm that, in the interval between the creation of nodes \(n-1\) and \(n\), takes \(k \cdot n\) revisit steps.

A rather obvious visual complexity indicator, even simpler than the revisit indicator, consists of plotting the number of nodes in the trinet dual as a function of the algorithm steps. We call this the dual node count indicator, with the attribute “dual” often omitted. Recall that these nodes represent trinet faces. This indicator is a monotonic, non-decreasing function, since the rule Refin adds one node to the trinet dual (two nodes to the original trinet), and the rule Diags leaves the node count unaffected. In Sections 4 through 9 we mainly refer to the revisit indicator, since it confirms but also refines in interesting ways the classification induced by pure node counting.

### 4. Threshold 3: One-Dimensional Trinets, Simple Oscillators, and Trees

Figure 7 shows the revisit indicator for all the computations of \(\text{Length} = 500\), with \(\text{Threshold} = 3\)—a set of \(18 \times 9 = 162\) elements that we denote \(C[\text{Threshold} = 3, \text{Length} = 500]\). Figure 8 shows the corresponding final trinets. The numbers appearing at the left of each small diagram represent the highest current edge identifier used in the
computation: this number cannot exceed $3 \times \text{Length}$, since the initial trinet dual has three edges, and each step can at most contribute three new edges.

Figure 7. Revisit indicators for all threshold-3, length-500 computations.
Figure 8. Final trinets for all threshold-3, length-500 computations.
4.1 Constant Revisit Indicator: Periodic Trinet Sequences

The simplest type of computation corresponds to a constant revisit indicator. An example is the computation $c[3, \{1, 1\}, \_\_\_]$ (of unspecified length), in which, after one step, edge 5 becomes the current edge forever, and Diags is the only rule applied. In this case, the sequence of trinets has period 2 and oscillates between the tetrahedron and a square-like graph with two double edges; the tetrahedron happens to be the final trinet of the length-500 computation, as shown in the corresponding entry of Figure 8. Many similar cases of constant plots, involving a finite number of distinct current edge identifiers, occur in this computation class, as well as in subsequent ones; they all correspond to periodic sequences of bounded-size trinets and to graphs with very few nodes and edges in Figure 8. For example, in the computation $c[3, \{2, 3\}, \_\_\_\_\_\_]$, the current edge oscillates between 7 and 4, and the sequence of trinets has period 10 (or period 5, if node identities are ignored). Note that in this class the node count indicator must also be a constant function.

4.2 Linear Revisit Indicator: Regular, One-Dimensional, Growing Trinets

The next simple case, quite common too, is that of revisit indicators with linear growth. An example is the computation $c[3, \{1, 2\}, \_\_\_]$, in which the sequence of current edge identifiers gives a regular numeric sequence where every third natural number is skipped. The corresponding graph is the simplest one-dimensional, ladder-shaped trinet. Four consecutive trinets from this computation are shown in Figure 9. Node numbers are shown to help in understanding the growth mechanism.

Other simple one-dimensional patterns are observed. For example, the computations $c[3, \{12, 5\}, 60]$ and $c[3, \{13, 5\}, 130]$ yield the trinets shown in Figure 10, which grow linearly and regularly: the details of these structures are lost in the linear thumbnail diagrams of Figure 8.

In all linear cases shown so far, the growth takes place at one extreme of the graph. A slightly different growth pattern is achieved by the computation $c[3, \{5, 9\}, \_\_\_\_]$, whose revisit indicator is illustrated in more detail, with the corresponding one-dimensional trinet, in Figure 11. In this case the growth takes place in the central part of the trinet.

The second one-dimensional pattern found in this family of computations is the circle: four examples are shown in Figure 12. In the last case, the circle is formed after a relatively large initial transient phase; the portion of the trinet created in this phase is then permanently abandoned, and growth takes place at the extreme of the circle opposite to it, as suggested by the picture.
Figure 9. Four consecutive trinets from the computation $c[3, \{1, 2\}, \_]$.

$\begin{array}{cccc}
3 & 12 & 5 & 6 \\
1 & 2 & 4 & 7 \\
5 & 3 & 8 & 11 \\
6 & 9 & 10 & 12 \\
\end{array}$

Figure 10. One-dimensional final trinets of $c[3, \{12, 5\}, 60]$ and $c[3, \{13, 5\}, 130]$.

Figure 11. (a) Revisit indicator and (b) final one-dimensional trinet growing from its center.
Figure 12. (a) Revisit indicator and (b) final, circular one-dimensional trinet for four computations.

The simple linear and circular one-dimensional structures appear combined in c[3, {13, 9}, _] (Figure 13); in this case the active region is at their junction, and they grow at the same speed, providing a stable overall shape.

All the revisit diagrams of this group eventually exhibit the same linear growth; the node count grows linearly with the computation steps, all parts of the growing trinet are eventually abandoned, except, possibly, for a finite part, and the trinet is one-dimensional.
4.3 Nested Revisit Indicator: Oscillating, Segment-Circle, and Circle-Circle One-Dimensional Trinets

Twelve examples of nested revisit indicators are found in Figure 7: six are in column two and have *(RefinCode, DiagsCode)* pairs (3, 2), (8, 2), (12, 2), (13, 2), (14, 2), (17, 2), and six are in column four with codes (5, 4), (6, 4), (11, 4), (13, 4), (14, 4), (16, 4). The final trinets in Figure 8 fail to reveal the substantial difference between these computations and those in the previous group, but the revisit indicators are more informative. In particular, these diagrams indicate that the trinet growth process sweeps an increasingly larger portion of the net, by actually sampling all parts of it, except for case (3, 2), in which a slowly growing region is permanently abandoned. Two distinct types of dynamics emerge from these 12 computations that are described next.

**Segment-circle.** The first growth pattern is exhibited by five computations, with codes (12, 2), (13, 2), (17, 2), (13, 4), (14, 4). We call this pattern “segment-circle” because the trinet is formed by connecting a linear segment and a circle; this is similar to the trinet shown in Figure 13, except that both parts now grow and shrink, with opposite phase, so that the trinet oscillates smoothly between a purely circular and a purely linear form. Activity always takes place at the junction between the two structures. As observed in the previous cases, the microstructure of the segment and the circle is based on a variety of different, simple building blocks. As an example, Figure 14 illustrates computation \( c[3, \{14, 4\}, 2300] \).

Note the similarity between the revisit diagram of Figure 14 and Figure 6(a). For a better illustration of the dynamics of these trinets, a subsequence of several steps from the computation \( c[3, \{13, 2\}, \_] \) is shown in Figure 15.
Figure 14. Nested computation \( c[3, \{14, 4\}, 2300] \).

Figure 15. Steps of the computation \( c[3, \{13, 2\}, \_] \), showing circular and linear components that grow and shrink.

Circle-circle. The second growth pattern is exhibited by seven computations, with codes (3, 2), (8, 2), (14, 2), (5, 4), (6, 4), (11, 4), (16, 4). We call the pattern “circle-circle” because the trinet is formed by connecting two circles, that grow and shrink with opposite phase. Again, the growth always takes place at the junction between the two structures, and various types of simple building blocks are observed. Several steps of the computation \( c[3, \{6, 4\}, \_] \) are shown in Figure 16, where the microstructure is the same as in Figure 15.
The 12 computations with nested revisit indicators discussed are also directly identified by inspecting their node count indicators: out of the 162 threshold-3 elements they are precisely those that exhibit a regular staircase shape with a sublinear growth. A closer investigation of these data has revealed the following facts.

The eight computations with RefinCode, DiagsCode pairs (3, 2), (8, 2), (12, 2), (17, 2), (5, 4), (11, 4), (13, 4), (16, 4) exhibit identical node growth functions, although they yield trinets of different types: codes (3, 2), (8, 2), (5, 4), (11, 4), (16, 4) yield the same circle-circle trinet, and codes (12, 2), (17, 2), (13, 4) yield the same segment-circle trinet. Their node growth function is matched with excellent precision by the function \( f(x) = 3 + \sqrt{x} \), as shown in Figure 17. Recall that the initial trinet dual indeed has three nodes.

**Figure 16.** A few steps of the computation `c[3, {6, 4}, _]` showing a growing and a shrinking circle.

**Figure 17.** Node growth for eight threshold-3 nested computations and the function \( 3 + \sqrt{x} \).
Of the four remaining nested cases, those with code pairs (13, 2) and (14, 4) are of the segment-circle type, while (14, 2) and (6, 4) are of the circle-circle type. All four node growth functions are different, but they all approximate quite closely the \( O(n^{1/2}) \) growth of the previous group. Indeed, by using the *Mathematica* function *FindFit* over computations of length 10 000, and by using the parametric function \( f(x) = a + b \times x^c \), in all four cases a \( c \) exponent in the close proximity of 1/2 was found.

### 4.4 Radial Revisit Indicator: Tree-Like Irregular Trinets

Two computations in class \( C[\text{Threshold} = 3] \) exhibit revisit indicators that are slightly perturbed versions of a very regular pattern consisting of potentially infinite straight lines (“rays”) emanating from the origin: these have code pairs (2, 5) and (11, 5). Their corresponding trinets are tree-like irregular graphs, and the active point on them also moves quite irregularly, visiting every part infinitely often. The revisit indicator and final trinet for computation \( c[3, (2, 5), 2000] \) are shown in Figure 18. We had found a cleaner (i.e., not perturbed) version of this radial revisit indicator by using another trinet algorithm, as described in [2], and find it later in this paper with the present algorithm.

![Figure 18](image_url)

**Figure 18.** An infinite rays revisit indicator and the corresponding tree-like trinet.

These two cases also illustrate the usefulness of our revisit indicator: the pure node count indicator for them is basically linear, and would not be as effective as the infinite-radii pattern in discriminating them from the many other computations with a linear node count.

### 4.5 Revisit Indicators with Long Random Transients: Complex Trinets with Highways

By inspecting Figure 7, six computations in class \( C[\text{Threshold} = 3] \) exhibit a high degree of apparent randomness in their revisit indicator. They are all in column nine, and have code pairs (3, 9), (8, 9),
(11, 9), (14, 9), (16, 9), (17, 9). In fact, by looking at longer computations, all of them eventually stabilize to a regular growth pattern, called a “highway” in analogy with the phenomenon observed in some two-dimensional Turing machines. (The node count indicators in all these cases appear as roughly linear, even in the transient phase preceding the highway.)

For example, Figure 19 shows the periodic revisit indicator and periodic trinet for the computation $c[3, \{3, 9\}, \ 2000]$.

![Figure 19](image1.png)

**Figure 19.** A periodic computation with short transient and long period.

As another example, Figure 20 illustrates the computation $c[3, \{11, 9\}, \ 12000]$. More than 8000 steps are necessary for stabilizing the growth, which settles into what we have called a segment-circle pattern, with the active part at the junction of the two components. In fact, in spite of the possibly very long initial transient and period, these computations are not qualitatively different from those with linear revisit indicators discussed at the beginning of this section.

![Figure 20](image2.png)

**Figure 20.** A computation yielding a trinet which eventually settles to a segment-circle pattern with linear growth.

Finally, we investigated the computation $c[3, \{14, 9\}, \_ ]$. Running it for 160,000 steps allowed us to detect the periodicity of its revisit indicator, with a period of over 11,000 steps.
5. Threshold 4: Nested Trinets and Uniform Randomness

Similar to Section 4, Figure 21 shows the revisit indicator for all 162 computations in class $C[Threshold = 4, Length = 500]$, and Figure 22 shows the corresponding final trinets.

Figure 21. Revisit indicators for all threshold-4, length-500 computations.
Planar Trinet Dynamics with Two Rewrite Rules

Complex Systems, 18 © 2008 Complex Systems Publications, Inc.

Figure 22. Final trinets for all threshold-4, length-500 computations.
By inspecting the two figures, it is immediately clear that the large majority of these computations exhibit emergent features that are qualitatively the same as those observed in the previous class. After a brief overview of these cases, we can move on to the novel, most interesting ones.

We still have periodic sequences of bounded trinets, and one-dimensional trinets that grow linearly and without bound, as segments or circles. Interestingly, among the latter, the computation $c[4, \{17, 5\}, \_]$ provides a trinet whose uniformly growing structure appears similar to a circle with its diameter, so that its macrostructure reproduces the initial trinet: a two-node graph with three double edges. We also find two computations, namely $c[4, \{16, 2\}, \_]$ and $c[4, \{17, 2\}, \_]$, with nested revisit indicators and corresponding trinets that oscillate while growing, according to the already observed circle-circle pattern. As observed with $Threshold = 3$, we find one computation with a noisy, radial revisit indicator, namely $c[4, \{11, 5\}, \_]$, which yields an irregular tree-like trinet, similar to that obtained with the computation $c[3, \{11, 5\}, \_]$. Finally, the computations $c[4, \{11, 9\}, 500]$, $c[4, \{13, 5\}, 500]$, and $c[4, \{17, 9\}, 500]$, whose revisit indicators do not manifest any regularity in 500 steps, all eventually settle to a one-dimensional, periodic, unbounded trinet. We are left with three novel and quite interesting cases that are discussed next.

5.1 $c[4, \{16, 4\}, \_]$: Nested Binary Tree Trinet with a Circular Boundary

This computation exhibits a cleaner version of the radial revisit indicator, and the trinet now has a regular and nested structure, as shown in Figure 23. It is formed by a binary tree with a trivalent root, with the addition of edges interconnecting adjacent leaves in a circle. The same trinet was also obtained by the algorithm introduced in [2].

![Figure 23](image_url)
5.2 \( c[4, \{3, 2\}, \_]: \) Nested Binary Tree with an Oscillating, Circle-Circle Pattern

The thumbnail for the trinet of this computation, shown in Figure 22, misleadingly suggests a similarity with the previous computation \( c[4, \{16, 4\}, \_]. \) However, the nested revisit indicator (Figure 21) reveals rather different dynamics. In fact, the trinet oscillates while growing and resembles the already discussed circle-circle pattern (see Figure 16), except that now a nested structure is involved, rather than a simple circle.

5.3 \( c[4, \{17, 8\}, \_]: \) Randomized Square Root Growth

This computation is perhaps the most surprising we have found; the only similar case is \( c[5, \{9, 8\}, \_], \) to be discussed later. Figure 24 shows the revisit indicator, the final trinet, and the node count as a function of the algorithm steps for \( c[4, \{17, 8\}, 6000]. \) Recall that we count the number of nodes in the trinet dual, corresponding to the number of faces in the original trinet. This function is then matched against the function \( f(\text{steps}) = 3 + \sqrt{2 \times \text{steps}}, \) which also exactly characterizes the regular, circular grow-and-revisit algorithm introduced in Section 3. Statistically, the growth process is such that, between two new trinet face creations, a number of revisits is performed that equals the current number of faces. Figure 25 shows similar data for a computation of length 100 000.

The ability of this computation to revisit its past uniformly, densely, and indefinitely, while exhibiting random-like dynamics, is indeed quite remarkable.
Figure 24. (a) Revisit indicator, (b) final trinet, and (c) node growth for c[4, {17, 8}, 6000].

Figure 25. (a) Revisit indicator, (b) final trinet, and (c) node growth for c[4, {17, 8}, 100000].
6. Threshold 5: Second Case of Uniform Randomness

Most of what emerges in this class has been observed before. For any value of RefinCode in the range [1, 8], and for values 12 and 14, the computation is independent from the value of DiagsCode and yields a linear or circular, one-dimensional trinet. All other cases are illustrated in Figures 26 and 27.

Figure 26. Revisit indicators for all threshold-5, length-500 computations.

Figure 27. Final trinets for all threshold-5, length-500 computations.
RefinCodes 11 and 15, again regardless of the DiagsCode, yield plain, linear revisit indicators, but the corresponding trinet structure are now nested, a combination that was not observed in previous classes. The same trinet structure can therefore be obtained by different revisit policies, and, correspondingly, in a different number of steps. Figure 28 shows three different computations with different revisit indicators that produce the same trinet in, respectively, 22, 22, and 85 steps. Nodes have been labeled to show the different orders in which the graphs were created.

Figure 28. Three computations that yield the same trinet.

No nested revisit indicator of the types seen before (e.g., that of computation \( c[3, \{3, 2\}, \_] \) or \( c[3, \{5, 4\}, \_] \)) is found in this class. But we do find an unperturbed radial revisit indicator for \( c[5, \{16, 4\}, \_] \) which corresponds to a nested trinet.

Complex Systems, 18 © 2008 Complex Systems Publications, Inc.
A peculiar tree-like trinet is obtained for \( c[5, \{17, 2\}, \_]; \) the revisit indicator and the trinet are shown in Figure 29. (In this case the sublinear, node growth function for the dual graph is approximated by \( f(\text{steps}) = 5.31 + 1.57 * \text{steps}^{0.65} \).)

As observed for \( \text{Threshold} = 4 \) computations, all six revisit indicator thumbnails that appear as random in Figure 26, corresponding to code pairs \((13, 5), (17, 4), (17, 6), (17, 8), (17, 9), (18, 8), \) end up settling into a regular behavior. But case \((17, 8)\) is the only one for which the revisit indicator stabilizes to a square root growth pattern. The last, most interesting case, is discussed next.

### 6.1 \( c[5, \{9, 8\}, \_]\): Second Case of Randomized Square Root Growth

This is the only other example, similar to case \( c[4, \{17, 8\}, \_]\), of a computation which exhibits a dense, random but uniform revisit indicator, with node growth well approximated by a square root function. Figures 30 and 31 show the revisit indicator, the final trinet, and the node growth function, with approximating functions for computations of lengths 6000 and 100 000, respectively.
Figure 30. (a) Revisit indicator, (b) final trinet, and (c) node growth for $c[5, [9, 8], 6000]$.

Figure 31. (a) Revisit indicator, (b) final trinet, and (c) node growth for $c[5, [9, 8], 100000]$. 

*Complex Systems, 18* © 2008 Complex Systems Publications, Inc.
7. Threshold 6: Regular and Irregular Two-Dimensional Grids

For $\text{Threshold} = 6$ and higher, the computations for $\text{RefinCode}$ values in range $[1, 8]$, and values $11, 12, 14, \text{and} 15$, appear exactly the same as those obtained for $\text{Threshold} = 5$, and are (individually) independent from $\text{DiagsCode}$ values. The six interesting values left for $\text{RefinCode}$ are illustrated in Figures 32 and 33.

![Figure 32](image)

*Figure 32.* Revisit indicators for all threshold-6, length-500 computations with $\text{RefinCodes}$ 9 through 18.

![Figure 33](image)

*Figure 33.* Final trinets for all threshold-6, length-500 computations with $\text{RefinCodes}$ 9 through 18.

Most of the computations in $C[\text{Threshold} = 6]$ exhibit the already discussed emergent features. For example, computations $c[6, \{9, 8\}, _{\_}], c[6, \{10, 5\}, _{\_}], c[6, \{13, 4\}, _{\_}], c[6, \{17, 2\}, _{\_}]$, and $c[6, \{18, 8\}, _{\_}]$, with irregular thumbnails, all end up settling into reg-
ular behavior, possibly with long initial transients. For example, $c[6, \{9, 8\}, \_\_]$ takes about 35,000 steps to stabilize.

However, three novel cases are observed that produce, for the first time in our investigation, two-dimensional trinets. They deserve special attention.

### 7.1 $c[6, \{10, 2\}, \_\_]$: Hexagonal Grid with Three Central Pentagons

The trinet produced by this computation is a two-dimensional, hexagonal grid that develops around a nucleus of three pentagons, as shown in Figure 34. The active point is always at the border of the graph. The fact that this border grows with the graph itself explains the peculiar shape of the revisit indicator, with three slightly divergent radii, and a growing part of the net being eventually abandoned.

![Figure 34. (a) Revisit indicator, (b) hexagonal grid, and (c) dual node count for $c[6, \{10, 2\}, 200]$.](image)

For comparison with the two other two-dimensional trinet computations, it is useful to analyze the distribution of polygon sizes. For the computation $c[6, \{10, 2\}, 3000]$, the following distribution is observed in the final trinet:

$$\{\{3, 3\}, \{4, 1\}, \{5, 93\}, \{6, 1453\}, \{98, 1\}\}$$

where $\{x, y\}$ indicates that there are $y$ faces with $x$ edges. Note the presence of a large external face with 98 sides.
7.2 \(c[6, \{13, 3\}, \_]: \text{Irregular Trinet Based on a Hexagonal Grid}\)

Unlike the case in Section 7.1, the trinet produced by this computation exhibits an intrinsically asymmetric structure, as shown in Figure 35. The distribution of face sizes for a computation of length 3000 is:

\[
\{3, 6\}, \{4, 1\}, \{5, 24\}, \\
\{6, 979\}, \{7, 7\}, \{8, 7\}, \{9, 2\}, \{11, 1\}.
\]  

(11)

It is clear that the largest part of the graph is a hexagonal grid, with 979 hexagons, but some larger faces are also present. Interestingly, a large external face is now missing, and this is not surprising if we consider the complex revisit indicator, which reveals randomness and fairness in revisiting all parts of the growing net, although traces of regularity and symmetry are also visible. Note that the trinet is drawn as two superimposed layers of roughly the same number of faces.

![Figure 35.](image)

Figure 35. (a) Revisit indicator, (b) hexagonal grid, and (c) dual node count for \(c[6, \{13, 3\}, 3000]\).

7.3 \(c[6, \{18, 9\}, \_]: \text{Hexagonal Grid with One Central Pentagon}\)

The trinet produced by this computation is a two-dimensional hexagonal grid that develops around one pentagon (Figure 36). The distribution of face sizes for a 3000 step computation is:

\[
\{3, 73\}, \{5, 51\}, \{6, 1404\}, \{7, 70\}, \{194, 1\}.
\]  

(12)
A large, external face is again present. The active point is always at
the border of the graph, and the growth process is similar to that of
the earlier computation c[6, (10, 2), _].

Figure 36. (a) Revisit indicator, (b) hexagonal grid, and (c) dual node count
for c[6, (18, 9), 200].

8. Thresholds 7, 8, and 9: Further Regular Two-Dimensional Grids

Class C[Threshold = 7] presents further types of nested trinets, both
with linear (e.g., c[7, (9, 9), _]) and with radial (e.g.,
c[7, (10, 2), _]) revisit indicators, and two more cases of two-dimen-
sional regular grids: c[7, (9, 2), _], which gives a pure hexagonal
grid, and c[7, (18, 9), _], which gives a hexagonal grid with one cen-
tral septagon. Both are illustrated in Figure 37.

No other two-dimensional regular trinet is found for Threshold val-
ues 8 and 9, while nested trinets are still present.
Figure 37. (a) Revisit indicators and (b) hexagonal grids produced by \((7, 9, 2), 200\) and \((7, 18, 9), 200\).

9. Infinite Threshold

The case \(\text{Threshold} = \infty\) is interesting because the algorithm is forced to always apply the \text{Refin} rule. The resulting computations are illustrated in Figures 38 and 39, where "*" stands for any value of \text{DiagCode} — a value that the algorithm never uses.

Figure 38. Revisit indicators for all computations with \(\text{Threshold} = \infty\) and \text{RefinCodes} 1 through 18, of length 500.
Figure 39. Final trinets for all computations of length 64, with Threshold = \infty and RefinCodes 1 through 18.

Note that the trinets refer, in Figure 39, to computations of length 64 only; they evenly split into six linear, six circular, and six nested graphs. The regular, radial revisit indicator of \( c[\infty, \{10, 1\}, \_\] is such that each edge (with identifier) in the set

\[
\{1, 2\} \cup \{3k + 1 | k = 1, 2, \ldots\}
\]  

(13)

appears infinitely often in the diagram, although at an exponentially decreasing rate. More precisely, denoting by \( s[e, n] \) the step (number) at which edge \( e \) is the current edge for the \( n^{\text{th}} \) time, the following holds for all visited edges as identified earlier:

\[
s[e, n] = 2s[e, n - 1] + 1 \quad (n > 1)
\]  

(14)

where \( s[1, 1] = 1, s[2, 1] = 2, \) and \( s[3k + 1, 1] = 2(k + 1), k = 1, 2, \ldots \). The arithmetic progression of initial edge occurrences, combined with the geometric progression of subsequent appearances of individual edges, determines the characteristic pattern of virtually infinite radii emanating from the origin.

10. Conclusions

In this paper we introduced an original algorithm for the creation of dynamic planar trivalent networks (trinets), and have exhaustively explored all the classes of its computations corresponding to values in the range 3 through 9, and to infinity, of a Threshold parameter. A number of quite interesting phenomena have emerged, although it is still unclear whether considering finite values beyond Threshold = 9 could yield qualitatively new features. Among the expected results we found plenty of computations that yield periodic sequences of bounded trinets, as well as sequences of one-dimensional trinets that grow without bound, where stabilization to regular, linear growth
may occur after very long transient phases characterized by pseudorandom dynamics.

More interestingly, we have found complex but still regular (nested) computations, with trinets that grow while oscillating between linear and ring structures based on simple building blocks, and computations that produce two-dimensional trinets based on the hexagonal grid. All of the latter exhibit a rather regular, roughly circular shape, and a regular growth pattern; but the computation \( c[6, \{13, 3\}, ~] \) is an exception and yields a smoothly growing trinet with an irregular shape, no especially large “external” face, and irregular motion of the control point.

But in our opinion the most interesting computations are \( c[4, \{17, 8\}, ~] \) and \( c[5, \{9, 8\}, ~] \). Their revisit indicators reveal a surprising ability to densely and fairly revisit the past, while exhibiting pseudorandom dynamics. Graph size, as a function of the number of algorithmic steps, grows as \( O\left(\sqrt{\text{steps}}\right) \). It is likely that this combination of randomness and fairness, guaranteed by an extremely simple algorithm that operates on a purely local basis, could find some useful application, still to be investigated.

In the introduction we listed the differences between our algorithm and the techniques proposed in [1] for animating trivalent networks. Our previous proposal for trinet computation [2] was different from the one presented here in the following aspects.

- We used only the \( \text{Refin} \) rule (this can now be obtained as a special case by setting \( \text{Threshold} = \infty \)).
- We used a rather different rule for driving the control point, based on rotations by a constant number of steps around the current node of the dual graph.
- We did not convert duals into primal form. In spite of the conceptual equivalence between the two forms, looking at the original trinet has been practically more helpful for spotting patterns such as oscillating rings.

A Demonstration of the algorithm described in this paper is available at the Wolfram Demonstrations Project site [4].

Much more remains to be done.

- \( \text{Loop edges} \). Ways for handling trinets with loop edges should be investigated. This may lead to considering new forms of degenerate triangles, and perhaps even to difficulties in keeping simple geometric interpretations of the manipulated data structures. In fact, interesting developments might derive from relaxing or abandoning those interpretations, and concentrating just on abstract data structures and operations. This may also help expose possible bridges with other simple computational systems.

- \( \text{Dimensionality} \). We have found many trinets for which the attribution of dimensionality 1 or 2 is obvious, but what about all of the other graphs? In the rather uninteresting cases of tree-like trinets, nodes grow exponentially with the distance from a given reference node. The
identification of a dimensionality for the finite, irregular subtrinets corresponding to the initial phase of eventually periodic computations is not of much interest. But what about the irregular trinets of the two computations $c[4, \{17, 8\}, _]$ and $c[5, \{9, 8\}, _]$ with random revisit indicators? A difficulty here derives from their slow, square-root node growth: in both cases, 100 000 step computations yield trinets with less than 1000 nodes, and, due to this limitation, the analysis of internode distances has not led to clear results. Finally, one might perhaps associate different dimensionalities to the same trinet, depending on the observation scale, since some trinets may exhibit different structures at different levels. This would perhaps offer some bridge toward physical theories that envisage a multidimensional space—notably string theory—with a distinction between extended and compacted dimensions. More generally, it seems desirable to investigate possible connections between trinet mobile automata computations and some of the quantum gravity theories proposed by physicists in the past few decades. A wide-spanning bibliographical review of theories concerned with the small scale structure of spacetime is found in [5].

- Relativistic, subjective views. A research track that we consider of highest priority is concerned with the introduction of a relativistic view of trinet computations, based on suitable notions of a spacetime/causal network. The trinet diagrams we have shown in this paper, if at all relevant to the understanding of real physical phenomena, would only represent an external view of a dynamic physical space (a sort of “God’s eye” view), while the spatial evolution perceived by an internal observer, one who is himself part of the universe, would be mediated by the causal relations between observation events. It is quite straightforward to define a causal network for the rewrite events of our algorithm, along the lines discussed in [1], chapter 9. Then, taking the point of view of a trinet face $f$, we could define discrete time, relative to $f$, in terms of the sequence of updatings of $f$, based on the assumption that a face, regarded as the smallest perceptive unit, does not experience anything, thus no progress of time, between two consecutive updates of $f$. Based on this notion of time, and taking into account the complete causal network of updating events, the idea would be to create a sequence of suitably defined “pictures” of the universe as perceived by $f$ at successive instants of its time. This sequence would represent the correct, internal view of the produced dynamic space, and the one to be appropriately compared with physical reality as we perceive it. We are particularly interested in applying this analysis to the computations $c[4, \{17, 8\}, _]$ and $c[5, \{9, 8\}, _]$, whose randomness and fairness might prove essential for guaranteeing the equivalence of all possible observers.

Acknowledgment

We express our gratitude to Marco Tarini, at the Institute of Information Science and Technologies “A. Faedo”, for several discussions on trivalent network representation.
